

While we're on the topic of terminology, it's worth mentioning two other terms that are often used interchangeably, but that we will use more carefully. We'll reserve the term *packet switch* to mean a general packet-switching device that transfers a packet from input link interface to output link interface, according to the value in a field in the header of the packet. Some packet switches, called **link-layer switches** (examined in Chapter 5), base their forwarding decision on values in the fields of the link-layer frame; switches are thus referred to as link-layer (layer 2) devices. Other packet switches, called **routers**, base their forwarding decision on the value in the network-layer field. Routers are thus network-layer (layer 3) devices, but must also implement layer 2 protocols as well, since layer 3 devices require the services of layer 2 to implement their (layer 3) functionality. (To fully appreciate this important distinction, you might want to review Section 1.5.2, where we discuss network-layer datagrams and link-layer frames and their relationship.) To confuse matters, marketing literature often refers to "layer 3 switches" for routers with Ethernet interfaces, but these are really layer 3 devices. Since our focus in this chapter is on the network layer, we use the term *router* in place of *packet switch*. We'll even use the term *router* when talking about packet switches in virtual-circuit networks (soon to be discussed).

### Connection Setup

We just said that the network layer has two important functions, forwarding and routing. But we'll soon see that in some computer networks there is actually a third important network-layer function, namely, **connection setup**. Recall from our study of TCP that a three-way handshake is required before data can flow from sender to receiver. This allows the sender and receiver to set up the needed state information (for example, sequence number and initial flow-control window size). In an analogous manner, some network-layer architectures—for example, ATM, frame relay, and MPLS (which we will study in Section 5.8)—require the routers along the chosen path from source to destination to handshake with each other in order to set up state before network-layer data packets within a given source-to-destination connection can begin to flow. In the network layer, this process is referred to as *connection setup*. We'll examine connection setup in Section 4.2.

#### 4.1.2 Network Service Models

Before delving into the network layer, let's take the broader view and consider the different types of service that might be offered by the network layer. When the transport layer at a sending host transmits a packet into the network (that is, passes it down to the network layer at the sending host), can the transport layer rely on the network layer to deliver the packet to the destination? When multiple packets are sent, will they be delivered to the transport layer in the receiving host in the order in which they were sent? Will the amount of time between the sending of two sequential packet transmissions be the same as the amount of time between their reception? Will the network

provide any feedback about congestion in the network? What is the abstract view (properties) of the channel connecting the transport layer in the sending and receiving hosts? The answers to these questions and others are determined by the service model provided by the network layer. The **network service model** defines the characteristics of end-to-end transport of packets between sending and receiving end systems.

Let's now consider some possible services that the network layer could provide. In the sending host, when the transport layer passes a packet to the network layer, specific services that could be provided by the network layer include:

- *Guaranteed delivery.* This service guarantees that the packet will eventually arrive at its destination.
- *Guaranteed delivery with bounded delay.* This service not only guarantees delivery of the packet, but delivery within a specified host-to-host delay bound (for example, within 100 msec).

Furthermore, the following services could be provided to a *flow of packets* between a given source and destination:

- *In-order packet delivery.* This service guarantees that packets arrive at the destination in the order that they were sent.
- *Guaranteed minimal bandwidth.* This network-layer service emulates the behavior of a transmission link of a specified bit rate (for example, 1 Mbps) between sending and receiving hosts. As long as the sending host transmits bits (as part of packets) at a rate below the specified bit rate, then no packet is lost and each packet arrives within a prespecified host-to-host delay (for example, within 40 msec).
- *Guaranteed maximum jitter.* This service guarantees that the amount of time between the transmission of two successive packets at the sender is equal to the amount of time between their receipt at the destination (or that this spacing changes by no more than some specified value).
- *Security services.* Using a secret session key known only by a source and destination host, the network layer in the source host could encrypt the payloads of all datagrams being sent to the destination host. The network layer in the destination host would then be responsible for decrypting the payloads. With such a service, confidentiality would be provided to all transport-layer segments (TCP and UDP) between the source and destination hosts. In addition to confidentiality, the network layer could provide data integrity and source authentication services.

This is only a partial list of services that a network layer could provide—there are countless variations possible.

The Internet's network layer provides a single service, known as **best-effort service**. From Table 4.1, it might appear that *best-effort service* is a euphemism for

Network Architecture	Service Model	Bandwidth Guarantee	No-Loss Guarantee	Ordering	Timing	Congestion Indication
Internet	Best Effort	None	None	Any order possible	Not maintained	None
ATM	CBR	Guaranteed constant rate	Yes	In order	Maintained	Congestion will not occur
ATM	ABR	Guaranteed minimum	None	In order	Not maintained	Congestion indication provided

**Table 4.1** ♦ Internet, ATM CBR, and ATM ABR service models

*no service at all.* With best-effort service, timing between packets is not guaranteed to be preserved, packets are not guaranteed to be received in the order in which they were sent, nor is the eventual delivery of transmitted packets guaranteed. Given this definition, a network that delivered *no* packets to the destination would satisfy the definition of best-effort delivery service. As we’ll discuss shortly, however, there are sound reasons for such a minimalist network-layer service model.

Other network architectures have defined and implemented service models that go beyond the Internet’s best-effort service. For example, the ATM network architecture [MFA Forum 2012, Black 1995] provides for multiple service models, meaning that different connections can be provided with different classes of service within the same network. A discussion of how an ATM network provides such services is well beyond the scope of this book; our aim here is only to note that alternatives do exist to the Internet’s best-effort model. Two of the more important ATM service models are constant bit rate and available bit rate service:

- **Constant bit rate (CBR) ATM network service.** This was the first ATM service model to be standardized, reflecting early interest by the telephone companies in ATM and the suitability of CBR service for carrying real-time, constant bit rate audio and video traffic. The goal of CBR service is conceptually simple—to provide a flow of packets (known as cells in ATM terminology) with a virtual pipe whose properties are the same as if a dedicated fixed-bandwidth transmission link existed between sending and receiving hosts. With CBR service, a flow of ATM cells is carried across the network in such a way that a cell’s end-to-end delay, the variability in a cell’s end-to-end delay (that is, the jitter), and the fraction of cells that are lost or delivered late are all guaranteed to be less than specified values. These values are agreed upon by the sending host and the ATM network when the CBR connection is first established.

- **Available bit rate (ABR) ATM network service.** With the Internet offering so-called best-effort service, ATM's ABR might best be characterized as being a slightly-better-than-best-effort service. As with the Internet service model, cells may be lost under ABR service. Unlike in the Internet, however, cells cannot be reordered (although they may be lost), and a minimum cell transmission rate (MCR) is guaranteed to a connection using ABR service. If the network has enough free resources at a given time, a sender may also be able to send cells successfully at a higher rate than the MCR. Additionally, as we saw in Section 3.6, ATM ABR service can provide feedback to the sender (in terms of a congestion notification bit, or an explicit rate at which to send) that controls how the sender adjusts its rate between the MCR and an allowable peak cell rate.

## 4.2 Virtual Circuit and Datagram Networks

Recall from Chapter 3 that a transport layer can offer applications connectionless service or connection-oriented service between two processes. For example, the Internet's transport layer provides each application a choice between two services: UDP, a connectionless service; or TCP, a connection-oriented service. In a similar manner, a network layer can provide connectionless service or connection service between two hosts. Network-layer connection and connectionless services in many ways parallel transport-layer connection-oriented and connectionless services. For example, a network-layer connection service begins with handshaking between the source and destination hosts; and a network-layer connectionless service does not have any handshaking preliminaries.

Although the network-layer connection and connectionless services have some parallels with transport-layer connection-oriented and connectionless services, there are crucial differences:

- In the network layer, these services are host-to-host services provided by the network layer for the transport layer. In the transport layer these services are process-to-process services provided by the transport layer for the application layer.
- In all major computer network architectures to date (Internet, ATM, frame relay, and so on), the network layer provides either a host-to-host connectionless service or a host-to-host connection service, but not both. Computer networks that provide only a connection service at the network layer are called **virtual-circuit (VC) networks**; computer networks that provide only a connectionless service at the network layer are called **datagram networks**.
- The implementations of connection-oriented service in the transport layer and the connection service in the network layer are fundamentally different. We saw in the previous chapter that the transport-layer connection-oriented service is
